1 LOG

1.1 PREDICTON

I am predicting that it will take me around **15 hours (average of 3 hours per programming language)** for me to learn LISP, ML, Erlang, functional JavaScript, and functional Scala and write a Caesar cipher in each language. Although I know that some of this assignment will be more challenging than Programming in the Past because functional programming requires a completely different mindset, I am already familiar with functional JavaScript and can use some of that knowledge to hopefully be able to quickly write the Caesar cipher in each language. Also, since I have already written the Caesar cipher in 5 languages, I know this assignment will be translating that work into a functional manner rather than trying to do it entirely from scratch.

1.2 PROGRESS LOG

Date	Hours Spent	Tasks / Accomplishments / Issues / Thoughts
March 6	3.5 hours	I wrote the Caesar cipher in LISP. It was a bit challenging because the syntax is not the cleanest and it is very difficult to find things online about it because every dialect does basic tasks different from one another.
March 7	3.5 hours	I wrote the Caesar cipher in ML. It was better documented than LISP, but more challenging to write because of its steeper learning curve.
March 8	0.25 hours	I had a lightbulb moment regarding everything I did poorly in ML and fixed it all up. I am much happier now that the code is more concise and flows a lot better.
March 8	2.5 hours	I wrote the Caesar cipher in Erlang and was pleasantly surprised by how easy it was relative to LISP and ML.

1.3 FINAL RESULTS AND ANALYSIS

2 COMMENTARY

2.1 LISP

2.1.1 MY THOUGHTS

LISP was a language I do not want to remember because it was nothing special relative to most other programming languages and had some features that were really frustrating to deal with. More specifically, the syntax for the language is too simplistic with intense operator overloading, confusing code organization, and poor online resources.

First, the syntax of LISP is extremely simple because parentheses are used everywhere. In LISP, lists are the main data structure and are denoted with parentheses. However, lists are used to make function calls, to define functions, and to store data, which makes it really confusing what is being stored within a list as there is nothing to differentiate these structures. Readability is seriously hurt from this as I still struggle to make the distinction between function calls and data after writing the code. Additionally, I found it difficult to write LISP code because the parentheses were challenging to manage and to keep clean. I tried my absolute best to keep parentheses lined up similar to how braces would be lined up in C family languages, but it still was not perfect and had some inconsistencies. Furthermore, messing up on the parentheses was a pain to debug because the LISP interpreter would throw a confusing error that meant absolutely nothing in helping me resolve the real problem.

Next, LISP has a very frustrating way to represent math operations. Since everything is a function in LISP, all math functions will take in 2 arguments, which can be the result of other math function calls. Similar to how a compiler works, the operations you want to do first have to be encapsulated so their output will be used by other functions. However, I had to learn this idea the hard way when I did $(- 90 (+ \text{diff } 1))$ instead of $(+ (- 90 \text{diff}) 1)$ to represent the formula $90 - \text{diff} + 1$. Naturally, I wanted to represent the subtraction first, so I naively placed it in the outermost function call, which was a really bad idea. Although minor, this change in operation order screwed up my program for a while and my friends had to remind me of the order of operations for why the 2 code chunks were different from each other. This syntax for specifying the order of operations for a formula does not make logical sense as the code no longer reads from left to right. Rather, one has to read it middle out (sadly not related to middle out compression in the TV show Silicon Valley) and do a depth-first in-order traversal of a mini syntax tree in their head to be able to actually understand what the code is doing. This amount of brain damage is completely overkill as one already has to treat functional logic completely differently from procedural logic, and this math function ordering does not help LISP in being user-friendly.

Lastly, LISP is a really old language, and, similar to BASIC, its many dialects made good online resources hard to come by. When searching for how to do something in LISP, whatever a website had as an answer was most likely wrong because the dialect that I was using (newLISP) did not support functionalities specific to some of the other dialects. Unfortunately, no website specified what dialect they were referring to, and doing the same search but with "newLISP" instead of "lisp" would just bring up the documentation for newLISP. At the end of the day, this documentation and the corresponding Wikibook were my best friends for writing the Caesar cipher in LISP as they provided me with the basics to get started, which I was able to modify for my own purposes.

Overall, LISP was not a terrible programming language as I really liked the succinctness of its functional style, but its overly simplistic syntax, annoying math functions, and limited resources made it challenging to work with. Relative to the Programming in the Past assignment, I would rank LISP similar to Fortran as they are both the grandfather languages of their respective domains and were not terrible and somewhat

useable, but I would never want to use them again if I do not have to.

Listing 2: LISP Output

2.2 ML

2.2.1 MY THOUGHTS

My Caesar cipher in ML will forever be remembered as the hackiest solution to a Caesar cipher. The language itself is just a cleaned up version of LISP with better documentation, but lack of sequential statements within functions and some weird math quirks made it one of the most rewarding challenges I have had in recent memory.

From my knowledge, ML functions do not support chaining multiple statements together. Rather, they only support returning the output from a single function call, which can have many nested function calls used as the input to the main function whose value is being returned. This made modularization difficult because it was always a big dilemma as to which chunks of logic could be put together versus separating them out into their own functions. As a fan of procedural programming, this was difficult to wrap my brain around as I struggled to match the data types together to be able to use the output from one function as the input to another. Furthermore, as an inexperienced functional programmer, I initially forced together a solution that worked but was very inefficient as I made a list of shift amounts and then zipped that list with the characters to create a list of tuples to pass into the performShift function. It was not until after a good night's rest when I realized that I could have just used an anonymous function and only map through the characters because then I could pass the shift amount in consistently without my crazy solution. Although my initial solution worked, I did make the change for code conciseness and because it was a better translation of the logic that was being done. This was also a lesson learned as the first solution that comes to mind when writing a functional program is not always the best answer because the logic has to be thought of in a more abstract way to come up with the best possible solution.

The other weird quirk was the syntax for negative numbers. When I was initially writing my ML program, I did not know how to represent a negative number in ML. Every time I wanted to use a - to represent negation, I was presented with a syntax error, most likely because - was a function for subtraction behind the scenes. Since I was already in the mindset to hack a solution together, I put a Band Aid on the problem by writing a function that negated a number by subtracting itself twice. I originally did not care about this function because it worked, but it did bother me because I knew that there was no way a programming language would make me write a negate function just to be able to represent a negative number. Similar to the previous problem with the hacky map function, I played around in ML's interactive mode for a couple minutes the next day to find out that it uses ~ instead of - to represent negative values. Although this is a tiny quirk of ML, it really bothered me because the writability was harmed due to the language not able to fully represent standard mathematical notation. Fortunately, this did not cause me nearly as much brain damage as the order of operations in LISP or trying to force multiple arguments into a map function in ML, but it was something to note because it was initially a key part in my program until I fixed it for clarity in the code.

Despite my annoyed experience writing the Caesar cipher in ML, I did have some good moments writing it. First, I love the type safety of the language as every variable and function is strictly defined. This is crucial for functional languages because it makes the code self-documenting and I know exactly what data type a function expects and what I will be receiving back as a return value. My other positive note was

specific to the Standard ML of New Jersey, but its interactive mode proved to be extremely useful when I was trying to figure out what functions were available to me. For instance, if I typed the command "open String;", I was presented with a full list of every string function in ML with definitions for the expected data types of the arguments and the return type. I did not dive deeper to find formal function definitions with verbose descriptions of what a given function did, but the basic definitions were enough for me as I was able to find what I was looking for and quickly added it to my code.

ML is in a weird place for me because it was more challenging than LISP because of the lack of sequential statements within a function, but I preferred its syntax and tooling over LISP. In other words, although my experience in LISP was better than ML, I would pick ML over LISP if I had to write a program in a functional language because its syntax is cleaner and significantly more readable and has better tooling and documentation compared to LISP.

2.3 ERLANG

2.3.1 MY THOUGHTS

Erlang was a language that I was not expecting to like, but I really enjoyed my time working in Erlang. The language does come with some problems, such as it not being strongly typed and performs implicit type conversions and variables are all immutable, but the syntax is overall really clean and easy to follow.

My only serious issue with Erlang was the implicit type conversion from a string to an integer. Erlang does not support strings and, instead, treats a string as a list of characters, which are just numbers behind the scenes. Thus, when I wrote the `performShift` method, I passed in the string/list and it automatically treated the data as an integer instead of a character. This is extremely dangerous because I never told it to make the conversion and was expecting to see individual characters. Unfortunately, this problem is empha-

sized more because Erlang is not strongly typed, so I never had an opportunity to state what data type I wanted each variable to be. This hurts Erlang in all 3 aspects: readability, writability, and reliability because the code is not self-documenting, it is harder to write when the variables are not strongly typed, and the language cannot be reliable if it does not tell the programmer that it is doing its own thing by making the conversions on its own.

One minor issue I had with Erlang was that all variables are immutable. Since Erlang supports sequential statements, I assumed that I would be able to combine a few statements to help create the logic for determining the value of a returned variable. Unfortunately, since variables are immutable, I had to be a little creative for how I could assign the proper value in one statement compared to in multiple steps. This is an extremely minor complaint on my part as it did not seriously impact my experience with Erlang.

Aside from the issues with the type conversions, Erlang's syntax is extremely clean and very easy to follow. I also appreciated how everything in Erlang requires recursion. When writing the Caesar cipher in LISP and ML, I was extremely caught up in the notion of using the map functionality to call a function many times and feel that I did not use recursion enough for those solutions. Erlang forces you to use recursion for literally everything as the functions to loop through the string and the solve shift amounts were done via recursion. Recursion is extremely easy to read, and the writability is stronger for Erlang for the consistency and minimal feature multiplicity with recursion being the way. This is the way, the Erlang way.

Overall, Erlang was actually really fun to use. Its syntax was really easy to learn, which helped me quickly and efficiently write my Caesar cipher. Despite the weird type conversions, Erlang is at least consistent about its weirdness and does not do anything unexpected once you start to learn how the language really works. The best part of Erlang was undoubtedly all of the recursion and how easy it was to be able to implement this form of logic within the program.
